(Received 16 July 2010; published 27 August 2010)

We perform a quantum simulation of the Ising model with a transverse field using a collection of three trapped atomic ion spins. By adiabatically manipulating the Hamiltonian, we directly probe the ground state for a wide range of fields and form of the Ising couplings, leading to a phase diagram of magnetic order in this microscopic system. The technique is scalable to much larger numbers of trapped ion spins, where phase transitions approaching the thermodynamic limit can be studied in cases where theory becomes intractable.

At the pinnacle of quantum information science is the full scale quantum computer,1 where applications such as Shor’s factoring algorithm2 can provide an exponential speedup compared with any known classical approach. While large-scale quantum computers may not be available for some time,3 more restricted quantum computers known as quantum simulators look promising right now.4 As first considered by Richard Feynman,3 a quantum simulator controls interacting quantum bits (qubits) to implement evolution according to a known Hamiltonian.5 Then, by performing particular correlation measurements on the qubits, properties of certain Hamiltonians—such as their ground state—can be extracted, often more efficiently than any classical simulation of the underlying quantum system.6 A good example is a collection of interacting magnetic spins, where the Hamiltonian can easily be written down, yet the ground state of magnetic order cannot always be predicted, even with just a few dozen spins.8

In this Rapid Communication we simulate the Ising model with a transverse magnetic field and generate a phase diagram, using a system of N=3 trapped atomic ions. By adiabatically manipulating the Hamiltonian, we extract the phases of magnetic order in the ground state as a function of the transverse field and Ising couplings.9–11 While this system admits an exact theoretical treatment, it also represents a wide range of fields and form of the Ising couplings, leading to a phase diagram of magnetic order in this microscopic system. The competition between different parameters in Eq. (1) gives rise to a complex phase diagram. The 23 possible spin configurations are defined as two FM states, $|↓↓↓\rangle$ and $|↑↑↑\rangle$, two symmetric AFM states, $|↑↑↓\rangle$ and $|↑↓↑\rangle$, and four asymmetric AFM states, $|↑↑\downarrow\rangle$, $|↑↓\uparrow\rangle$, $|↓↑\uparrow\rangle$, and $|↓\uparrow\uparrow\rangle$, all defined along the x axis of the Bloch sphere. In Fig. 2, we plot a part of the theoretical phase diagram where the nearest-neighbor interactions are always FM ($J_2<0$). We prepare the system in the ground state of the transverse field ($B_z\gg|J_1|$), depicted by the solid circle (Fig. 1), and then adiabatically lower the field compared to the Ising couplings. When $B_z/|J_1|\ll1$ the Ising interactions determine both the form of the ground state and the energy spacing $\Delta_{\alpha\alpha}$ to the excited states(s).

In Fig. 1(a), the next-nearest-neighbor interaction is also FM ($J_2<0$). There are no level crossings with the ground state over the trajectory indicated by the arrow, thus if the evolution of the Hamiltonian is slow enough, the system remains in the ground state (solid black line). We can also change the sign of $B_z$ and adiabatically follow the highest excited level, as it exhibits the same structure as the ground state. In Fig. 1(b), $J_2>0$ and the next-nearest-neighbor interaction is antiferromagnetic (AFM). The gap at the crossover to magnetic order defined by the Ising couplings is ~15 times smaller than that of Fig. 1(a), requiring a slower change of $B_z/|J_1|$ to remain in the ground state.

The Hamiltonian is described by the equation

$$H = \sum_{i<j} J_{ij} \sigma_i^{(z)} \sigma_j^{(z)} + B_z \sum_i \sigma_i^{(z)}$$

with Ising couplings $J_{ij}$ between spins $i$ and $j$ and a uniform transverse magnetic field $B_z$, where Planck’s constant, $\hbar$, is set equal to one. For three spins along a symmetric one-dimensional chain, we define $J_1=J_{1,2}=J_{2,3}$ as the nearest-neighbor interaction strength and $J_2=J_{1,3}$ as the next-nearest-neighbor interaction, with $\sigma_i^{(z)}$ the Pauli-spin operator of the $i$th particle along the $\alpha$ direction. Figure 1 shows two energy spectra as a function of the scaled transverse field $B_z/|J_1|$ in the case of ferromagnetic (FM) nearest-neighbor interactions ($J_2<0$). We prepare the system in the ground state of the transverse field ($B_z\gg|J_1|$), depicted by the solid circle (Fig. 1), and then adiabatically lower the field compared to the Ising couplings. When $B_z/|J_1|\ll1$ the Ising interactions determine both the form of the ground state and the energy spacing $\Delta_{\alpha\alpha}$ to the excited states(s).
and radiofrequency ion trap and couple them through a rotation axis. These vibrational normal modes, having frequencies "clock" states \(J_i/|J_i| \sim 2\) and \(J_2/|J_1| \sim 0.9\). The arrow in both diagrams indicates the trajectory in the simulation, initialized at \(B_0/|J_1| \sim 10\). Under this condition, the initial ground state is an eigenstate of the second term in Eq. (1), a polarized state along \(B_0\). In both examples, at \(B_0/|J_1|\) some high-energy states cross, but the ground state (black solid line) has no level crossings with any excited state. Likewise, the highest energy state does not cross any other levels, allowing one to also adiabatically follow this state. The dotted lines represent excited states which are coupled to the ground state along the path. In the large field limit, the energy difference between ground and excited states \(\Delta e\) (here, scaled by \(\sqrt{B_0^2+J_1^2}\)) is proportional to \(B_0\) but as \(B_0/|J_1|\) crosses the spin-spin couplings determine the energy difference and the form of the ground state. In both (a) and (b), the final ground state is FM (defined along the \(x\) axis of the Bloch sphere), however in the case of (a), the gap to the nearest allowed excited state at the crossover is \(\sim 15\) times larger.

states. This effect arises because the pairwise interaction energy cannot be minimized individually, leading to a highly degenerate, or frustrated, ground state.\cite{11}

We experimentally simulate the transverse-field Ising model of Eq. (1) using cold trapped \(^{171}\text{Yb}\)\(^+\) ions,\cite{12} with the effective spin-1/2 system represented by the hyperfine “clock” states \(S_{1/2}(F=1, m_F=0)\) and \(S_{1/2}(F=0, m_F=0)\) denoted as \(\uparrow\) and \(\downarrow\), respectively,\cite{13} where \(\uparrow\) and \(\downarrow\) are \(\uparrow\) and \(\downarrow\). We confine \(N=3\) atomic spins in a linear radiofrequency ion trap and couple them through \(N\) collective transverse motional normal modes along one principal axis. These vibrational normal modes, having frequencies \((v_1, v_2, v_3) \sim (4.334, 4.074, 3.674)\) MHz, are each cooled to near the ground state and deeply within the Lamb-Dicke limit.\cite{10, 11}

The effective magnetic field \(B_0\), which produces Rabi oscillations between the two spin states, is generated by uniformly illuminating the ion chain with two Raman laser beams having a difference frequency at the hyperfine splitting, \(v_{HF}=12.642821\) GHz. For an individual beam detuning of \(\sim 1.8\) THz below the \(S_{1/2}^+\) \(S_{1/2}^0\) transition\cite{14} and a peak intensity of 10 W/mm\(^2\) each ion undergoes Rabi oscillations at a rate of \(\Omega \sim 1\) MHz and experiences a \(\sim 20\) kHz differential ac Stark shift.

FIG. 1. Energy level diagrams for Eq. (1) with two different types of spin-spin interactions. For both panels, the nearest-neighbor interactions are FM \((J_i<0)\), (a) The next-nearest-neighbor interaction is FM with \(J_2/|J_1| \sim -2\) and (b) AM with \(J_2/|J_1| \sim 0.9\). The arrow in both diagrams indicates the trajectory in the simulation, initialized at \(B_0/|J_1| \sim 10\). Under this condition, the initial ground state is an eigenstate of the second term in Eq. (1), a polarized state along \(B_0\). In both examples, at \(B_0/|J_1|\) some high-energy states cross, but the ground state (black solid line) has no level crossings with any excited state. Likewise, the highest energy state does not cross any other levels, allowing one to also adiabatically follow this state. The dotted lines represent excited states which are coupled to the ground state along the path. In the large field limit, the energy difference between ground and excited states \(\Delta e\) (here, scaled by \(\sqrt{B_0^2+J_1^2}\)) is proportional to \(B_0\) but as \(B_0/|J_1|\) crosses the spin-spin couplings determine the energy difference and the form of the ground state. In both (a) and (b), the final ground state is FM (defined along the \(x\) axis of the Bloch sphere), however in the case of (a), the gap to the nearest allowed excited state at the crossover is \(\sim 15\) times larger.

The spin-spin interaction \(J_{ij}\) is created by coupling the ions’ spin states through the normal modes of motion of the chain. The two Raman beams travel perpendicular to each other to have a wavevector difference \(\delta k\) along the transverse direction. The laser frequency of one of the two pathways is modulated to yield beatnotes (with respect to the nonmodulated beam) at frequencies \(v_{HF} \pm \mu\), imparting a spin-dependent force at frequency \(\mu\).\cite{15, 16} By controlling the beatnote detuning \(\mu\), we tailor the Ising couplings according to

\[
J_{ij} = \Omega_i \sum_m \frac{\eta_{m,0} \eta_{m,0} v_m}{\mu^2 - v_m^2}.
\]

Here, \(\Omega_i\) is the Rabi frequency of the \(i\)th ion. The Lamb-Dicke parameter for the \(m\)th mode of the \(i\)th ion is \(\eta_{i,m}=B_{i,m}(\delta k/\hbar)(4\pi M v_m)\), where \(b\) is the normal-mode transformation matrix and \(M\) the mass of a single ion. In the above expression, we assume \(|v_m-\mu| > \eta\Omega\), so that phonons are only virtually excited.

We initialize the spins along the \(B_0\) direction through optical pumping \((\sim 1\) μs) and a \(\pi/2\) rotation about the \(\pm x\) axis of the Bloch sphere. The simulation begins with a simultaneous and sudden application of both \(B_0\) and \(J_{ij}\), where \(B_0\) overpowers \(J_{ij}(B_0/|J_{ij}| \sim 10)\). A typical experimental ramp of \(B_0\) decays as \(B_0=ae^{-t/T}+b\) with a time constant of \(\tau \sim 30\) μs, varying from \(a \sim 10\) kHz to a final offset of \(b \sim 500\) Hz after \(t=300\) μs. By varying the power in only one of the Raman beams, this procedure introduces a change in the differential ac Stark shift of less than 2 Hz. We turn off the Ising interactions and transverse field at different \(B_0/|J_{ij}|\) end points along the ramp. We then measure the magnetic order along the \(x\) axis of the Bloch sphere by first rotating the spins by \(\pi/2\) about the \(y\) axis, and detecting the \(z\) component of the spins through spin-dependent fluorescence.\cite{15} By repeating identical experiments \(\sim 1000\) times, we obtain the probability for the system to be in a particular spin configuration. We collect fluorescence with a photomultiplier tube, exhibiting \(\sim 97\%\) detection efficiency per spin after 0.8 ms exposure.

This procedure is performed for nine different combinations of \(J_1\) and \(J_2\) set by the beatnote detuning \(\mu\) from Eq.
FIG. 3. (Color online) Experimental measurements of the phase diagram for Eq. (1) (solid bars) compared to the theoretical prediction from Fig. 2 (surface). The vertical amplitude is the FM order parameter $P_{(FM)}=P_{(J_{1})}+P_{(J_{2})}$. The ratio of $B_{s}/|J_{1}|$ was varied from $\sim 10$ to $\sim 0.1$ for $J_{2}/|J_{1}|$ values of $-1.3, -2.0, -3.6, 4.2, 2.0, 1.3, 0.92, 0.74$, and $0.62$. $J_{1}<0$ for all traces. (a) As $B_{s}/|J_{1}| \rightarrow 0$ in the region where $J_{2}/|J_{1}|<1$, we observe a smooth crossover to FM order. The filled circles and solid line are the data and theory for $J_{2}/|J_{1}|=-1.3$, respectively. (c) When changing $J_{2}$ for a fixed and small value of $B_{s}/|J_{1}|$ the system undergoes a sharp transition. The data (filled circles) shown is for a scan of $B_{s}/|J_{1}|=0.57$. The average deviation per scan of $B_{s}/|J_{1}|$ from the exact ground state is $\sim 0.09$.

(2). In Fig. 3 we present the results as a three-dimensional plot of the FM order parameter with the theoretical phase diagram (surface) in Fig. 2 superimposed on the data. The data are in good agreement with the theory (average deviation per trace is $\sim 0.09$) and shows many of the essential features of the phase diagram. As $B_{s}/|J_{1}|$ decreases, a smooth crossover from a nonordered state to FM order occurs in the region where $J_{2}/|J_{1}|<0$ [Fig. 3(b)]. As the number of spins increases, this is an example of a quantum phase transition. A first-order transition due to an energy level crossing is apparent [Fig. 3(c)] when changing $J_{2}$ for a fixed and small value of $B_{s}/|J_{1}|=0.57$. This transition is sharp, even in the case of three spins. The data [e.g., Fig. 3(b)] show small amplitude oscillations in the initial evolution due to the sudden application of the spin-spin interaction, which is held constant during the simulation to minimize variation in the differential ac Stark shifts. This limitation can be removed by choosing the Raman laser detuning such that contributions from the $^{12}P_{1/2}$ energy level lead to a minimum in the ratio of the differential ac Stark shift to the resonant Rabi frequency.17

We now investigate adiabaticity of the Hamiltonian trajectory $H(t)$, characterized by the condition

$$\frac{B_{s}(t)}{\Delta_{g}^{s}} \ll 1. \tag{3}$$

In this expression, the dimensionless quantity $\epsilon=\left|g(t)\frac{d}{dt}e(t)\right|$ characterizes coupling from the ground state $|g(t)\rangle$ to any excited state $|e(t)\rangle$ with energy gap $\Delta_{g}^{s}$. This parameter is small, of order unity for this simulation, but is peaked at a crossover in magnetic order, where the instantaneous eigenstates are most rapidly varying. Therefore, Eq. (3) states that to remain adiabatic, the slope of the time-dependent $B_{s}$-field profile must be shallow when the gaps in the energy spectrum are small [as in Fig. 1(b)], in particular, near a crossover (phase transition for large $N$).

In Fig. 4, we investigate this adiabatic criteria for two different types of next-nearest-neighbor coupling. In Fig. 4(a) all interactions are FM and $J_{2}/|J_{1}| \sim -2$ [as in Fig. 1(a)]. The dashed lines in the top panel are the adiabaticity parameter from Eq. (3) calculated over the trajectory for the two coupled excited states (recall Fig. 1). Due to the 500 Hz final offset of $B_{s}$, the simulation stops at $B_{s}/|J_{1}| \sim 0.5$. To examine
the behavior extended below this value, we calculate the criteria for an exponential ramp with a 100 μs time constant. This profile was chosen to overlap with experimental parameters for large $B_r/|J_r|$ and also reach $B_r=0$ in a typical simulation time ($\sim 300$ μs). The results indicate that Eq. (3) is satisfied over the trajectory; $\tilde{B}_r(t)e^{\Delta_{ge}^2}$ remains much less than one even with a maximum occurring at $B_r/|J_r| \sim 1$. To demonstrate the simulation is indeed adiabatic for these parameters, the measured probability $P(FM)$ (solid dots) is shown in the lower panel of Fig. 4(a). The black line represents the adiabatic ground state and the gray line is the theoretical expected probability including the experimental ramp. The dotted line in this figure is the theoretical state profile for simulations near the special point. In fact, to successfully evolve to the true ground state near $B_r=0$, the theoretical curve does not significantly deviate from the ideal ground state and the data are in good agreement with all three theory curves.

Figure 4(b) presents the case when the next-nearest-neighbor interaction is AFM and $J_2/|J_1| \sim 0.9$ [as in Fig. 1(b)]. When $B_r/|J_r| < 1$, $\tilde{B}_r(t)e^{\Delta_{ge}^2}$ reaches a maximum value of $\sim 0.6$, indicating that the probability for excitations will likely increase. This difference is because in this case the gap $\Delta_{ge}$ at the “critical” point is $\sim 15$ times smaller than that in Fig. 1(a). In contrast to the FM $J_2$ case, the theoretical probability curves shown in the lower panel of Fig. 4(b) predict significant diabatic effects when using this $B_r$-field profile for simulations near the special point. In fact, to successfully evolve to the true ground state near $B_r=0$, the simulation time (assuming same initial conditions and an exponential ramp of $B_r$) should be at least a factor of ten longer.

Because all the data lies outside of the region where the energy gaps are small, the diabatic excitations are minimal, but further experimental study is needed to precisely quantify this effect. One method to probe excitations, which may also be useful as $N \gg 1$, is to perform and then adiabatically reverse the experimental ramp and measure the probability of returning to the initial state. The main contributions to the overall data offset from theory shown in Figs. 3 and 4 are spontaneous emission due to off-resonant scattering (probability $\sim 15\%$ in 1 ms), imperfect optical pumping (state preparation), parasitic fields along the $x$ and $z$ axes, and state detection error. Additional phonon terms not appearing in the Hamiltonian of Eq. (1) are expected to contribute at a level under 2%.

As the number of spins $N$ grow, the technical demands on the apparatus are not forbidding. In particular, the expected adiabatic simulation time for this model is inversely proportional to the critical gap in the energy spectrum; for the transverse-field Ising model in a finite-size system, this gap decreases as $N^{-1/3}$. Scaling this system to accommodate long ion chains (approaching the thermodynamic limit) will allow investigation of behavior near critical points. This is interesting for $N \gg 20$, where general spin models become theoretically intractable. For instance, the Lanczos algorithm can be used to find low-lying states of a 30 spin/site problem if the $2^{30}$ element matrix is sparse. If one is interested in a non-sparse matrix, as is the case for the ion system with long-range magnetic coupling, the limiting number of spins is $\sim 20$. Theoretical investigations of dynamics limit the number of spins further.

We note that this approach to quantum simulation is versatile and may be extended to simulate Heisenberg or XYZ spin models using additional laser beams.
